Technical terms in this review

1. Prior distribution

A prior distribution is a probability distribution representing our beliefs about a parameter before observing the actual data. It represents our initial belief about the parameters of interest before observing any data.

Priors can be:

- Informative, reflecting previous studies or expert knowledge (e.g., Normal(0, 5));
- Weakly informative, providing mild regularization without strongly influencing the result (e.g., half-Cauchy(0, 0.5)); or
- Non-informative, aiming to have minimal impact (e.g., a uniform prior).

2. Posterior probability

The posterior probability is the updated probability after accounting for new data. It is a revised probability that takes into account newly available information. For example, researchers' initial belief about the chance that mobile-assisted learning is more effective than traditional learning could be changed after the experiment.

3. Posterior distribution

The posterior distribution reflects our updated belief about the parameters after observing the data. It combines the prior distribution with the likelihood of the observed data. It is a way to summarize what we know about uncertain quantities in Bayesian statistics.

4. Posterior mean

Posterior mean denotes the average value of the posterior distribution.

5. Credible interval

Credible intervals are intervals whose values have a posterior probability density, representing the plausibility that the parameter has those values. For example, a 95% credible interval indicates a 95% probability that the true parameter value falls within that interval, given the data and the prior.

6. Random-effects model

- $d_k \sim N(\delta_k, v_k)$: The observed effect size from study k (denoted as d_k) is assumed to be normally distributed around that study's true effect δ_k , with known sampling variance v_k . In other words, each study's published effect size bounces around its own true effect, with "noise" given by the study's precision (for example, how large the sample is or how reliable the measurements are).
- $\delta_k \sim N(\mu, \tau^2)$: The true effects δ_k vary from study to study and are assumed to be drawn from a normal distribution with overall mean effect size across studies (μ) and between-study variance τ^2 . That is, we assume the true effects themselves are not identical, but cluster in a normal "cloud" of width τ scattered around one central value (μ).
- Each observed effect size d_k from the k -th study was modeled as normally distributed around a true study-specific effect size δ_k , with a variance v_k computed from each study's reported standard deviations and sample sizes. The true effect sizes δ_k across all studies were assumed to be normally distributed around a single overall mean effect size μ , with variance τ^2 representing between-study heterogeneity.
